## Abstract

Long term mapping is the natural conceptual extension to existing mapping methods that are focused on mapping static environments. Mapping an area over a long time is a problem that if tackled efficiently will be a large step towards fully autonomous robots. Such methods address problems that existing methods do not such as memory bottlenecks and changes that occur in the map over time. As discussed in the literature lifelong mapping consists of two major subproblems. A compression problem as the size of the map increases over time, and a dynamic environment problem as the environment changes over time. This thesis investigates the application of non-parametric Bayesian methods and how such tools can be directed to tackle the compression subproblem of lifelong mapping methods. A novel method of pointcloud representation is presented and its results are applied to an extended Kalman filter algorithm; its compression strength and expressive power are analyzed as well as directions in which the method could be improved and extended to formulate a general solution to both the compression as well as the dynamic environment problem of lifelong mapping.

## 1. INTRODUCTION

Simultaneous Localization And Mapping(SLAM) is one of the fundamental challenges of autonomous systems[1]. In order for robots to be considered truly autonomous they have to be able to enter an unknown environment and map the structure while navigating in the environment. With solutions like EKF-SLAM[2] and FastSlam[40] we can now efficiently map unknown environments. The logical extension of methods that can map *static* environments for a *finite amount of time* are methods that remove those restrictions. The idea of lifelong learning in robots is not new[5], and in recent years research with a specific focus on lifelong learning in mapping[6] was introduced. Lifelong mapping introduces the concept of robots that are able to continuously map their environment and this leads to two basic extensions over existing methods: Mapping methods must be able to handle the memory needs of a constantly increasing in size environment and robust enough to be able to handle changes that occur in the environment over time.

The increasing need of memory resources brings in the spotlight one of the fundamental restrictions of autonomous systems, i.e. memory bottlenecks. In order to be able to map for an indefinite amount of time, an indefinite amount of memory is required. Since we cannot have an indefinite amount of memory, the need for methods that store environment information in a less costly manner rises. The problem then transposes to creating compressed representations of the environment that also retain a high amount of information from the initial structure.

As a result, lifelong mapping consists of two basic subproblems: a compression problem as the map increases over time and a dynamic environment problem as the environment changes over time[7]. In this project the focus will be directed on the compression problem of lifelong mapping. More specifically, how can Bayesian non-parametric methods be used to create compressed environment representations that still retain enough environment information to be used as reference points when performing SLAM. The following research questions have then to be addressed: Are such representations rich enough to be used as references points when performing SLAM? Are the methods fast enough to be used in online SLAM problems? Is the compression created by the methods significant? Since different sensors require different mapping approaches the focus will be directed towards algorithms that use RGBD sensors like Microsoft Kinect to perform the mapping.

Since its introduction in 2010 Microsoft Kinect[25] has revolutionized RGBD devices with its low price range and high quality sensors. It came as no surprise that research in pointclouds, the cloud representation system of Kinect, has increased since then. Many libraries that enable the user to perform tasks from feature extraction to plane segmentation[12] in pointclouds are currently available. In the field of robotics, many teams are using the Kinect sensors to perform simultaneous localization and mapping[13]. The goal of this thesis is to introduce a novel compressed representation of pointclouds in order to tackle the first part of lifelong mapping problems while using Bayesian methodologies.

Dirichlet processes and Dirichlet process mixture models [26] are the cornerstone of Bayesian non-parametric statistics. The strength of those models lies in the fact that they allow the model's mixture components to grow as much as needed so as to best fit the data. The dynamic number of components in combination with different prior choices leads to very flexible models that can be used in a very large area of applications from topic modeling[43] to speaker diarization[45]. The main motivation of this project is to use such methods as a means of creating compressed

representations of the environment that also retain enough expressiveness to be used as reference points when performing SLAM. In this paper a novel compressed representation of a cloud is introduced and its results are analyzed both towards their robustness and expressive ability. The strengths and weaknesses of the method are analyzed and directions on how the method could be extended to tackle the rest subproblems of lifelong mapping are given in the discussion section.

The rest of the paper is structured as follows. Section 2 will present relevant literature review, section 3 will introduce the theories behind the model, section 4 will define the model, section 5 will show experimental results of the method. Section 6 will discuss specific behaviours of the method and, finally, section 7 will conclude with a short summary and future directions in which the method could be improved.

## 2. LITERATURE REVIEW

Literature review will be focused on 4 related sub fields: Object based SLAM, methodologies point-cloud object segmentation, non-parametric Bayesian methods and the correspondence problem in SLAM.

Given that the basic motivation of the project is to create representations of objects within the cloud, methods that use objects to perform SLAM are relevant. The second part of the literature research is focused on pointcloud segmentation and the features that need to be extracted from a cloud to minimize information loss. The third part of the research is focused on non-parametric Bayesian methods and the clustering tools they provide. Finally, literature review is focused on the correspondence problem in SLAM. As one of the fundamental problems that need to be solved in order to have robust SLAM algorithms, it is imperative the correspondence problem be solved efficiently.

### 2.1. Object based SLAM

Object based SLAM introduces a specific category of mapping problems where objects are used as reference points while navigating through the environment. Salas-Moreno et al.[14] define a method of performing object based SLAM for specific classes objects. The objects are identified by a camera that is on top of the robot. By having a model of pre-trained objects, SLAM can be performed on environments the robot knows what objects to expect. Castle et al. use object recognition to perform object based SLAM with the use of a hand-held cameras. Selvatici et al.[15] use a similar approach while exploiting structural information such as object height and position within the room. That way a couch that is a large object situated in floor level is easier to be recognized. Choudhary et al.[17] use pointclouds and an object database to match objects currently seen with known objects within their database. They use omnimap[27] as their mapping method and as a representation a combination of the downsampled voxel grids with additional normal and curvature information. Finally, all their operations are done in the non-planar components of the pointcloud. Jensfelt et al[15] present an object based approach to SLAM where the robot can manipulate the objects of the map. They use camera pictures as input and receptive Field Histogram as the method to abstract the camera input and extract features for their object matching algorithm. Their approach is proposed as a solution to a service robot scenario. MonoSLAM[19] introduces a method of performing SLAM using a monocular camera. Seongyong Koo et al.[20] introduce a method of unsupervised object individuation from RGB-D image sequences. They cluster their initial cloud into candidate objects using Euclidian clustering and proceed to extract features like the Euclidian distance(L2) and the Kullback-Leibler distance between pointcloud objects. They use IMFT to solve their tracking problem.

The common base of such methods, with the exception of [20], is that they treat the problem of object based SLAM as a classification task. More specifically, the robot cannot navigate in environments where it cannot find such objects. The approach presented in this paper introduces a general and unsupervised method of using environment signatures as reference points to perform SLAM.

## 2.2. Point Cloud Object clustering

Point cloud clustering tools enable the user to cluster clouds in objects, or segments of structure that "make sense". The robustness of the clustering varies with respect to the method used the features it requires as well as the application domain. Trevor et al.[29] take positional information, Euclidean distances and the normal of points to as input to their function and output segments that are part of the same object. PCL library[12] introduces methods like Euclidean clustering and conditional Euclidean clustering that use a number of heuristics that take normal as well as curvature information to extract segments in the pointcloud that represent objects. Furthermore, there is a lot of research on segmentation of pointclouds in scenes, with the emphasis usually put on extracting geometric primitives[30],[31] using cues like normals and curvature. Rabbani et al.[23] introduce a new method of object segmentation using KNN as their base algorithm. They also present a very informative literature review along with the strengths and weaknesses of existing methods. Finally Triebel et al.[32] introduce a general clustering framework that does not rely on plane segmentation. Instead of segmenting the plane by using classical approaches like RANSAC or MLASAC they introduce a framework where they make no assumptions regarding plane data.

In this thesis an alternative novel clustering approach will be introduced that will use Bayesian non-parametric methods as its base.

## 2.3. Non Parametric Bayesian methods

Dirichlet processes and Dirichlet process mixture models are the cornerstone of Bayesian statistics. In this project the focus is directed towards the clustering methods that are being introduced by those tools. Radford M. Neal[38] with his paper regarding MCMC methods for Dirichlet process mixture models made the definitive step towards Dirichlet process mixture models(DPMM's) receiving a lot of attention. Since then, a variety of approaches for inference on such models has been introduced with MCMC methods, and variational inference(VI) methods being two prominent such approaches. Variational inference for DPMM's, introduced by Jordan et al.[39] introduces deterministic tools to perform inference and approximate the posterior distribution and marginals of a dataset. Blei et al.[43] introduced LDA as a method to perform topic modelling. Teh et al.[41] introduce a hierarchy on the inference process by introducing the Hierarchical Dirichlet process. Particle filter approaches have also been established. Doucet et al.[42] introduce Sequential Monte Carlo as a fast way to approximate inference. Dirichlet process mixture models are a very active research field and covering it is beyond the scope of this thesis.

In this thesis SMC samplers were used due to their robustness as well as their inherent extensiveness. A detailed description on the mechanisms of sequential samplers will be given in the theory section.

## 2.4. Correspondence

In its general definition, the correspondence problem refers to the problem of ascertaining which parts of one image correspond to which parts of another image, where differences are due to movement of the camera, the elapse of time, and/or movement of objects in the photos. Under the object based SLAM context, it refers to the problem of identifying objects as ones that have been

encountered before during the mapping process. In that direction, Cree et al.[34] create a histogram of line segments of each landmark and compute their root mean square error. They then proceed to calculate their RGB signature to calculate the distance between different landmarks. Low et al.[35] match Scale Invariant Feature Transform (SIFT) features, an approach which transforms image data into scale-invariant coordinates relative to local features. Lamon et al.[36] store a database of fingerprints which indicate the location in the robot's environment. The features are ordered and stored at a database as they appear in the robot's immediate surroundings. A new fingerprint is computed for each new view and matched against existing ones. Finally, in Seghal et al.[37] an extension of SIFT descriptors to 3D data and pointclouds is given.

In this thesis the correspondence problem is solved using a simple decision layer that compares current environment signatures to past ones.

### 3. THEORY BACKGROUND

An introduction to the Dirichlet Distribution and Dirichlet process mixture models will be given. Finally, the Generaly Polya urn model will be presented as it serves as the base to the sampler presented in the model section.

#### 3.1. Dirichlet Distribution

An example of a *probability mass function*(pmf) is an ordinary six-sided dice. To sample from the pmf, you cast the dice and get a number from 1 to 6. One important property of pmfs given from real dice is that they are not uniformly weighted due to the manufacturing process not being perfect. A bag of dice can then be considered as an example of a random pmf. To sample from this random pmf, you have to put your hand in the bag and draw a die, and the result of this drawing process is itself a probability distribution. A Dirichlet distribution is an object that can be used to model the randomness of such objects whose domain is itself a probability distribution i.e it is a distribution of distributions.

Formally, a probability mass function with  $k$  components lies on the  $(k-1)$  dimensional probability simplex, which is a surface in  $\mathbb{R}^k$  denoted by  $\Delta_k$  and defined to be the set of vectors whose  $k$  components are non-negative and sum up to 1, that is:  $\Delta_k = \{q \in \mathbb{R}^k \mid \sum_{i=1}^k q_i = 1, q_i \geq 0 \text{ for } i = 1, 2, \dots, k\}$ .  $\Delta_k$  is itself a  $(k-1)$  dimensional object lying in the  $k$  dimensional space.

**Dirichlet distribution:** Let  $Q = [Q_1, Q_2, \dots, Q_k]$  be a random pmf, that is,  $Q_i \geq 0$  for  $i = 1, 2, \dots, k$  and  $\sum_{i=1}^k Q_i = 1$ . In addition, suppose that  $\alpha = [\alpha_1, \alpha_2, \dots, \alpha_k]$ , with  $\alpha_i \geq 0$  for each  $i$ , and let  $\alpha_0 = \sum_{i=1}^k \alpha_i$ . Then  $Q$  is said to have a Dirichlet distribution with parameter  $\alpha$ , which we denote by  $Q \sim Dir(\alpha)$ , if it has  $f(q; \alpha) = 0$  if  $q$  is not a pmf, and if  $q$  is a pmf then:

$$f(q; \alpha) = \frac{\Gamma(\alpha_0)}{\prod_{i=1}^k \Gamma(\alpha_i)} \prod_{i=1}^k q_i^{\alpha_i - 1}$$

The first two cumulants of the distribution are the following:

$$E[\alpha_i] = \frac{\alpha_i}{\alpha_0}$$

$$Cov(Q_i, Q_j) = \begin{cases} \frac{-\alpha_i \alpha_j}{\alpha_0^2 (\alpha_0 + 1)} & \text{if } i \neq j \\ \frac{-\alpha_i (\alpha_0 - \alpha_i)}{\alpha_0^2 (\alpha_0 + 1)} & \text{if } i = j \end{cases}$$

The mean and variance formulas help understand how the changing the  $\alpha$  vector affects the behaviour of the distribution as to where the density is located as well as the variance in the pmfs sampled. The following graphs display the difference of behaviour on samples from Dirichlet distributions with different initial alpha values.

Random samples from a Dirichlet distribution are presented in Fig.1. It must be noted that every point within the simplex can be considered itself a pmf since its components add up to one. Furthermore, for an  $\alpha = [c, c, c]$ ,  $c \geq 0$ , the density is symmetric towards the center of the simplex; for the special case of  $\alpha = [1, 1, 1]$  where  $c=1$  is displayed at Fig.1(a) where the initial choice of the  $\alpha$  vector results in a uniform distribution of points over the probability simplex. As  $c$  increases

the distribution is concentrated towards the center of the simplex. The behaviour of the density changes when the  $\alpha$  vector is not symmetric, when there is a shift in density towards the higher parameter, as is shown in Fig.1(b) and Fig.1(c). Finally, when the values of the vector are smaller than 1, the density of the distribution is shifted towards the vertices of the simplex as is shown in subplot Fig.1(d).

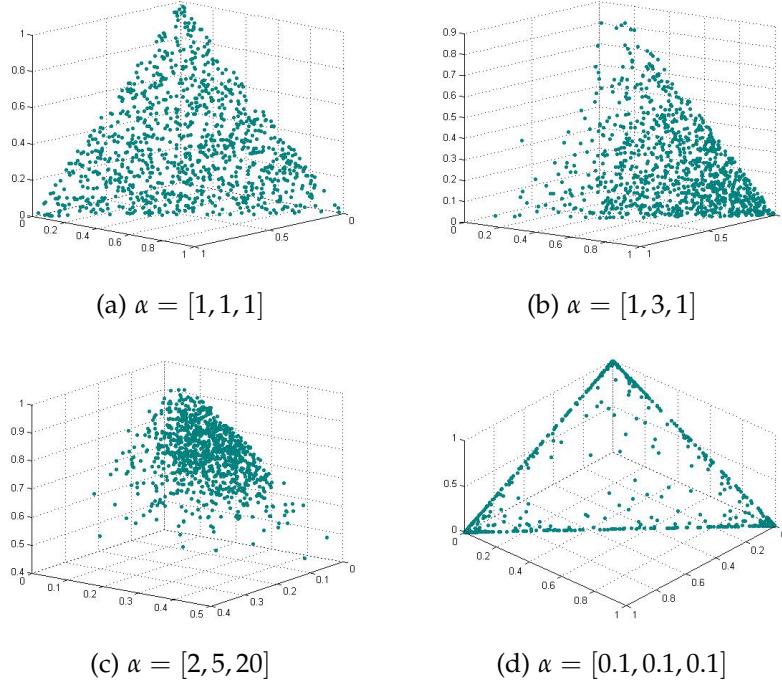

Figure 1: Different behaviour the distribution for different initial parameters of the  $\alpha$  vector

One important property of the Dirichlet distribution is that it serves as a conjugate prior for the probability parameter  $q$  of the multinomial distribution.

That is, if  $(X|q) \sim \text{Multinomial}_k(n, q)$  and  $Q \sim \text{Dir}(\alpha)$  then  $(Q|X = x) \sim \text{Dir}(\alpha + x)$

### 3.2. Sampling methods

Two basic sampling methods from the Dirichlet Distribution will be presented: Stick breaking process, and Polya's urn.

#### 3.2.1 Stick Breaking Process

The stick breaking process can be thought of as follows: Imagine breaking a unit length stick into  $k$  such that the  $k$  pieces follow a  $\text{Dir}(\alpha)$  distribution. Such samples can be created by the following procedure:

- **Step 1:** Simulate  $u_1 \sim Beta(a_1, \sum_{i=1}^k a_i)$ , and set  $q_1 = u_1$ . That's the first piece of the stick, with the remaining piece having length of  $1 - u_1$
- **Step 2:** For  $2 \leq j \leq k - 1$ , if  $j-1$  pieces, with lengths  $u_1, u_2, \dots, u_{j-1}, \dots$  have been broken off, the length of the remaining stick is  $\prod_{i=1}^{j-1} (1 - u_i)$ . We simulate  $u_j \sim Beta(a_j, \sum_{i=j+1}^k a_i)$  and set  $q_j = u_j \prod_{i=1}^{j-1} (1 - u_i)$ . The length of the remaining part of the stick is  $\prod_{i=1}^j (1 - u_i)$
- **Step 3:** The length of the remaining piece is  $q_k$ .

Since the last part of the stick will always be created so that we end up with a valid pmf, it is made explicit how the density of the Dirichlet is a  $k - 1$  dimensional object lying in the  $k$  dimensional space. Fig.2 shows realizations of the stick breaking process in  $R^3$  and the similarities between the stick breaking sampling method and the probability simplex presented in the previous section are shown.

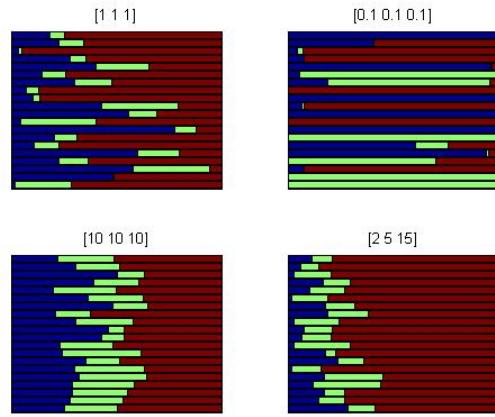

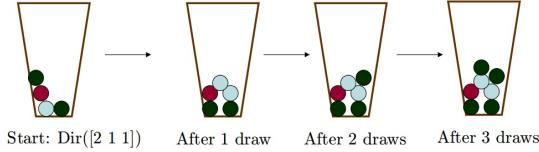

Figure 2: Stick breaking construction

As expected, an initial  $\alpha$  vector of  $[1,1,1]$  results in a uniform distribution of weights and. Furthermore, as the weights increase we have a more balanced distribution of weights as shown for the case of Fig.2([10,10,10]) and this balance is shifted towards the higher weight when the initial vector is not symmetric as shown in Fig.2([2,5,15]). Finally, an initial vector of weights  $< 1$  results in single values dominating the simplex.

### 3.2.2 Polya's Urn

The second method of sampling from a Dirichlet distribution is by using an urn model. In probability theory and statistics, an urn problem is an idealized mental exercise in which some objects of real interest are represented as colored balls in an urn or other container. More specifically, Polya's urn model depicts a random process whose realizations are realizations of a Dirichlet distribution. Suppose that you want to generate  $Q \sim Dir(\alpha)$ . To start, we put  $\alpha_i$  balls of colour  $i$  for  $i = 1, 2, \dots, k$  in an urn, as shown in Fig.3. It must be noted that  $\alpha$  can be fractional and even irrational(!). At each iteration we randomly draw a ball from the urn and put it back in the

 Figure 3: Polya's urn for  $\alpha=[2 1 1]$ 

urn with an extra ball of the same colour as well. As we iterate this procedure an infinite amount of times, the proportions of the balls of each colour will converge to a pmf that is a realization of from the distribution  $Dir(\alpha)$ .

The procedure can be then described as follows:

- **Step 1:** Set a counter  $n=1$ . Draw  $X \sim \alpha/\alpha_0$ .
- **Step 2:** Update counter to  $n+1$ . Draw  $X_{n+1}|X_1, X_2, \dots, X_n \sim \alpha/\alpha_{n0}$ , where  $\alpha_n = \alpha + \sum_{i=1}^n \delta_{X_i}$  and  $\alpha_{n0}$  is the sum of the entries of  $\alpha_n$ . Repeat step 2 an infinite number of times.

As the number of iterations of Step 2 approaches infinity, the proportions of ball colors in the simplex will be a realization from the distribution  $Dir(\alpha)$  with an initial vector  $\alpha$ .

### 3.3. Dirichlet Process

The Dirichlet process was formally introduced by Thomas Ferguson in 1973 and serves as an extension to the Dirichlet distribution in modelling infinite sets of events. More specifically, in the introductory example, a six sided dice was described. If instead of a six sided dice a dice with an infinite amount of sides was used, the Dirichlet Distribution could not handle the infinite sample space. A Dirichlet process is a random process whose realizations are distributions over an arbitrary and possibly infinite sample space. To make the infinity assumption manageable, the Dirichlet process restricts the class of distributions it can handle to a specific set: Discrete distributions over the infinite sample space that can be written as an infinite sum of indicator functions which can be formally presented as:

$$P(B) = \sum_{k=1}^{\infty} p_k \delta_{y_k}$$

Where  $p_k$  is the mixture weight and  $\delta_{y_k}$  is an indicator function such that  $\delta_{y_k}(B) = 1$  if  $y_k \in B$  and  $\delta_{y_k}(B) = 0$  otherwise. This formulation makes explicit the fact that realizations of a Dirichlet process are discrete distributions.

Formaly, the DP is defined as follows: Let  $\mathcal{X}$  be a set and let  $\mathcal{B}$  be an  $\sigma$ -algebra on  $\mathcal{X}$ . Let  $(\mathcal{X}, \mathcal{B})$  denote the collection of probability distributions on set as  $\mathcal{P}$ .  $\mathcal{P}$  is a Dirichlet Process as with a strength parameter  $\alpha$  and a base distribution  $H$  on  $(\mathcal{X}, \mathcal{B})$  if for any finite measurable partition  $\{B_i\}_{i=1}^k$  of  $\mathcal{X}$ , the random vector  $((P(B_1), \dots, P(B_k))$  has a Dirichlet distribution with parameters  $(\alpha H(B_1), \dots, \alpha H(B_k))$ . The mean and the covariance of a Dirichlet process are defined as:

- $E[G(A)] = \alpha H(A)$ . The base distribution can be though of as the mean of the Dirichlet process

- $\mathcal{V}[G(A)] = \frac{H(A)(1-H(A))}{\alpha+1}$ . The strength parameter  $\alpha$  can be thought of as the inverse covariance of the Dirichlet process.

### 3.4. Sampling methods

Two methods for sampling from a Dirichlet process will be presented: the Chinese Restaurant Process, the Stick Breaking Process.

#### 3.4.1 Chinese restaurant process

Polya's Urn and the stick breaking process are two names of the same process. The Chinese restaurant process paradigm is similar to the Polya's urn and it is defined as follows: Imagine a restaurant with an infinite number of tables, each with infinite capacity. At time  $t=1$ , the first customer enters the restaurant and sits at table 1 with probability 1. For every next step, the customer can either

- Choose an unoccupied table with probability  $\propto \frac{\alpha}{n-1+\alpha}$
- Choose occupied table  $k$  with probability  $\propto \frac{c}{n-1+\alpha}$  where  $c$  is the number of people currently sitting at that table

If you let an infinite number of customers enter the restaurant, the proportions of people sitting on each table will be a realization from a Dirichlet process with strength parameter  $\alpha$ .

It can be seen that there is a positive reinforcement effect in this process, that is the more people already sitting at a table, the bigger the probability that more people will be sitting into that table in the future. It can also be proved that the number of tables grows  $\propto \alpha \log(n)$  where  $n$  is the number of customers in the restaurant. Fig.4 visualizes the progression of the process as more people enter the restaurant.

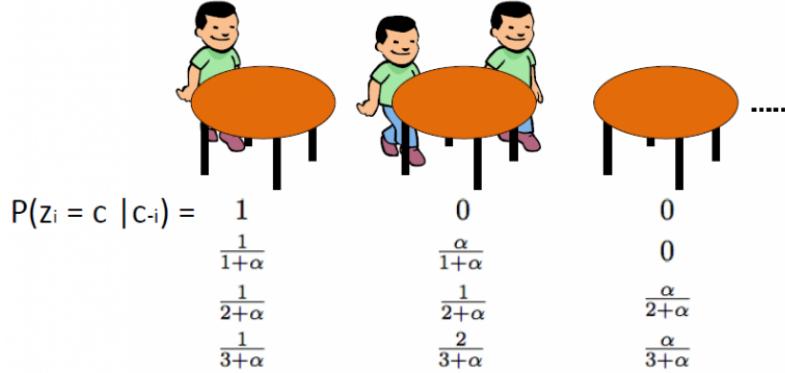

Figure 4: The CRP process

One important property of this procedure is that the  $n$ th customer has the same probability to sit on the same table as any other customer of the table. That is the number of people seating on

table 1 is on average the same as the number of people seating on table  $k$ ! This very interesting and counter intuitive(at first) property of the exchangeable data and understanding this is crucial on building intuition regarding the behaviour of exchangeable random variables.

### 3.4.2 Stick Breaking

Measures drawn from a Dirichlet distribution are discrete with probability 1. This property is made explicit by the stick breaking construction. The construction is based on the independent sequences of i.i.d. random variables  $(\pi'_k)_{k=1}^{\infty}$  and  $(\phi_k)_{k=1}^{\infty}$  defined as follows:

$$\pi'_k | \alpha_0, G_0 \sim Beta(1, \alpha_0) \quad \phi_k | \alpha_0, G_0 \sim G_0$$

This can be defined as follows: Draw  $\pi'_k$  as a Beta random variable. Draw  $\phi_k$  from  $G_0$ . Now define a random measure  $G$  as:

$$\pi_k | \pi'_k \prod_{l=1}^{k-1} (1 - \pi'_l) \quad G = \sum_{k=1}^{\infty} \pi_k \delta_{\phi_k}$$

The first part of the stick will have length  $\pi'_k$  and the conditional length given all the previous draws is given by  $\pi_k$ . Finally, the distribution created is given as an infinite sum of indicator functions given by  $G$ . Fig.5 displays a Dirichlet Process's realization from a stick breaking process with a Gaussian base distribution. Different parameter values for strength parameter  $\alpha$  directly affect the distributions output. As the alpha parameter is increased, the realization of the distribution will be closer to the base distribution. Furthermore, this picture also shows that the distribution created from the infinite sum of indicator function is a discrete distribution. Finally, when  $G$  is generated using a stick breaking process with a strength parameter  $\alpha$ , it can be written in shorthand as:  $G \sim GEM(\alpha)$

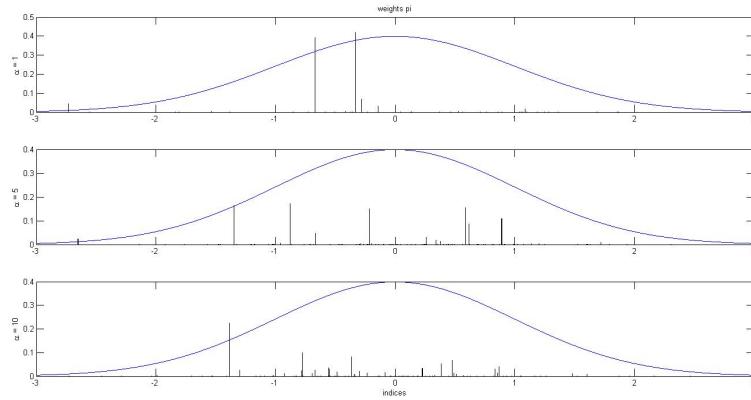

Figure 5: The stick breaking process.

### 3.5. Dirichlet process mixture models

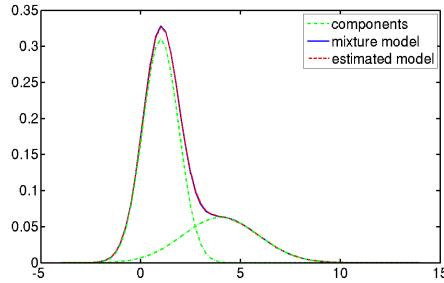

Figure 6: Mixture model

One of the most important properties of those objects is that they can serve as a non-parametric prior to mixture models. A typical 1D mixture model that represents data coming from a mixture of two one-dimensional Gaussian distributions is shown in Fig.6.

Mixture models can be considered as the Bayesian approach to clustering, and one of the most important applications of the Dirichlet process is to serve as the non-parametric prior on the parameters of such models. In particular, suppose that observations  $x_i$  arise from the following model:

$$\theta_i | G \sim G, x_i | \theta_i \sim F(\theta_i) \quad (1)$$

Where  $F(\theta_i)$  denotes the distribution of the observation  $x_i$  given  $\theta_i$ . The factors  $\theta_i$  are conditionally independent given  $G$ , and the observation  $x_i$  is conditionally independent of the other observations given the factor  $\theta_i$ . When  $G$  is distributed according to a Dirichlet process, this model is referred as a Dirichlet process mixture model and its representation is shown in Fig.7. The number of distributions that underlie the data can be mapped to the number of tables within a Chinese restaurant process, and the mixing proportions are proportional to the number of people sitting in every table.

Since  $G$  can be represented using a stick-breaking construction, the factors  $\theta_i$  take on values  $\phi_k$  with probability  $\pi_k$ . We can denote this using  $z_i$  as an indicator variable which takes on positive values and is distributed according to  $\pi$ . Hence, an equivalent representation of a Dirichlet process mixture model is given by the following conditional distributions:

$$\begin{aligned} \pi | \alpha_0 &\sim GEM(\alpha_0) & z_i | \pi &\sim \pi \\ \phi_k | G_0 &\sim G_0 & x_i | z_i, (\phi)_{k=1}^{\infty} &\sim F(\phi_{z_i}) \end{aligned} \quad (2)$$

The infinite limit of finite mixture models is taken when we let the number of components into a model to reach infinity. An infinite mixture model assumes that the data come from an infinite number of distributions.

This means that in such models the number of components from which the data are generated can be infinite. In such models it is important to notice in a dataset of size  $n$ , the data come from

at most  $n$  components. This is an important property of infinite mixture models and is exploited when performing posterior inference.

### 3.6. Inference

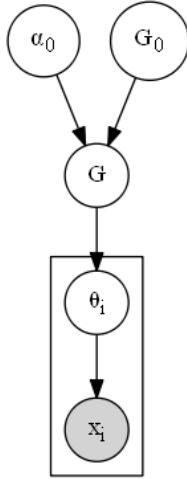

Figure 7: A Dirichlet process mixture model.

Statistical inference is the process of deducing properties of an underlying distribution by analysis of data. Inference can be considered as the inverse procedure presented in the plate in Fig.7; the same graphical process with the arrows facing the opposite direction. Statistical inference techniques can be categorized into 3 families: MCMC, Variational inference and SMC methods. The literature on such methods is extensive and covering it is beyond the scope of this project; for the purpose of this project an SMC sampler will be defined in detail in the model definition section.

### 3.7. Generalized Polya Urn

Dirichlet process priors have been widely used in the literature as non-parametric Bayesian tools to estimate the number of clusters in the data[46]. Dependent Dirichlet Processes(DDP) extend those tools by allowing the clusters in the data to vary with some variance over time by introducing dependencies on the data. The DDPs are a natural extension of the Dirichlet processes in domains where data cannot be considered exchangeable.

A DDP is also known as Generalized Polya Urn[47]. The most important property of this model is that it randomly deletes partitions of clusters on every iteration.

This Generalized Polya Urn distribution also has the shorthand notation GPU( $\alpha, \rho$ ) and can be described as follows: At time point  $t$  given the clusters at  $t - 1$  and the data  $N_{t-1}$  perform the following: for every cluster and every point within that cluster the point will stay in the cluster or be deleted from it; the probability of a point being deleted from the cluster is proportional to either the size of the cluster or a constant value  $\rho < 1$ [47]. After the deletion takes place, each point at time  $t$  is being assigned to a new cluster  $c_{t,n}$  with probability proportional to the size of the cluster at time  $t - 1$  or assigned to a new cluster with probability proportional to strength parameter  $\alpha$  of the prior Dirichlet Process. Cluster sizes are then updated accordingly.

The GPU can be described using the Chinese restaurant process paradigm as follows: At time  $t$ , customers are seating at several tables in the restaurant. Each customer decides if he/she will remain at table with probability  $p$  or definitely leave the table with probability  $1 - p$ . Each customer makes his/her decision and leaves or remains seated. Each table occupied is moved according to the number of customers still occupying the table or is deleted if is currently empty. A new customer then enters the restaurant and either chooses to sit on one of the existing tables with probability proportional to the number of customers sitting at that specific table or choose table a new with probability to the strength parameter  $\alpha$  of the prior Dirichlet process.

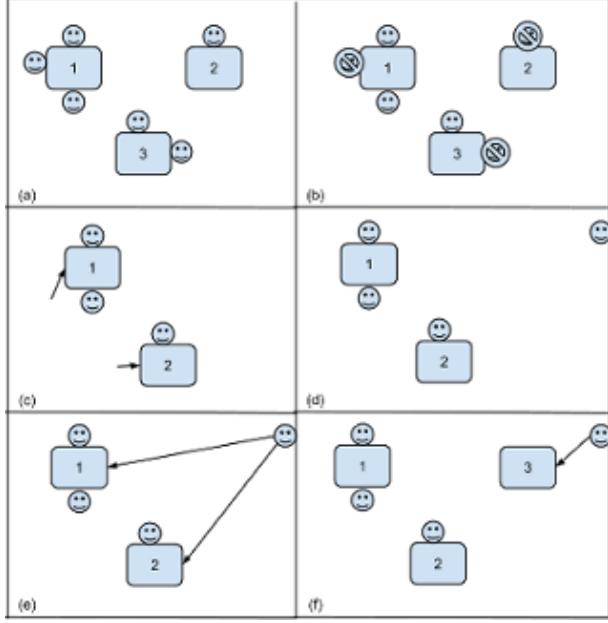

Figure 8: GPU as a function of CRP

Algorithm 1 describes the following process: At time step  $t$  given cluster assignments at time  $t - 1$  and data  $N_{t-1}$  perform the following: for every cluster and every point within that cluster the point will either stay in the cluster or be deleted from it; the probability of a point being deleted from the cluster is proportional to either the size of the cluster or a constant value  $\rho < 1$ [47]. Cluster sizes are then modified with respect to the number of points that were deleted from each cluster. After the deletion takes place, each point at time  $t$  is being assigned to a new cluster  $c_{t,n}$  with probability proportional to the size of the cluster at time  $t - 1$  after the deletion step or be assigned to a new cluster with probability proportional to strength parameter  $\alpha$  of the prior dependent Dirichlet process. Cluster sizes are then updated accordingly.

---

**Algorithm 1** GPU

```

1: procedure GPU( $t$ )
2:   for  $k = 1, \dots, K_{t-1, N_{t-1}}$  do
3:     Draw  $\Delta s_{t-1}^k \sim \text{Binom}(s_{t-1, N_{t-1}}^k, \rho)$                                  $\triangleright$  Number of elements to delete
4:     Set  $s_{t,0}^k = s_{t-1, N_{t-1}}^k - \Delta s_{t-1}^k$ 
5:   end for
6:   for  $n = 1, \dots, N_t$  do
7:     Draw  $c_{t,n} \sim \text{Cat}\left(\frac{s_{t,n-1}^1}{\alpha + \sum_k s_{t,n-1}^k}, \frac{s_{t,n-1}^2}{\alpha + \sum_k s_{t,n-1}^k}, \dots, \frac{s_{t,n-1}^{K_{t,n-1}}}{\alpha + \sum_k s_{t,n-1}^k}\right)$ 
8:     If  $c_{t,n} \leq K_{t,n-1}$  set :  $s_{t,n}^{c_{t,n}} = s_{t,n-1}^{c_{t,n}} + 1, K_{t,n} = K_{t,n-1}$ 
9:     If  $c_{t,n} > K_{t,n-1}$  set :  $s_{t,n}^{c_{t,n}} = 1, K_{t,n} = K_{t,n-1} + 1$ 
10:   end for
11: end procedure

```

## 4. MODEL DEFINITION

The model definition section is structured as follows: An introduction to the general pipeline that will serve as the compressed sensor model of the EKF SLAM module is presented first. Every non-trivial component of the pipeline is then analysed in detail with respect to the operations it serves.

### 4.1. General pipeline

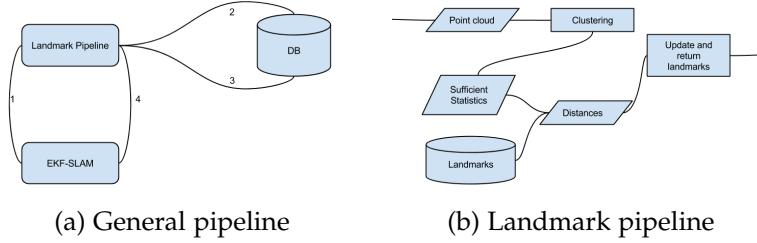

Figure 9: General landmark update pipeline

The general flow of operations that defines the basic communication between the pipeline and the EKF module is presented in Fig. 9. During step 1 the EKF-SLAM module requests new observation readings given the cloud currently read by the sensors and the position of the robot. The pipeline takes the cloud readings, extracts clusters and returns the landmarks currently being observed while taking into account landmarks that were observed in the past. Landmarks and clusters are identical concepts representing a different layer in the pipeline. More specifically, clusters are output from the sampler and are given as an input of landmarks to the EKF module. Fig. 9 shows a more detailed view of the computations of the pipeline. The algorithmic procedure shown in Algorithm 2 analytically.

---

#### Algorithm 2 Landmark Layer

---

```

1: procedure GETLANDMARKIDs(pointCloud, existingLandmarks)
2:   cloudReduced  $\leftarrow$  downsample(pointCloud)
3:   features  $\leftarrow$  extractFeatures(cloudReduced)
4:   landmarks  $\leftarrow$  cluster(features)
5:   for landmarks as landmark do
6:     (similarity, landId)  $\leftarrow$  calcBestSim(landmark, existingLandmarks)
7:     if similarity  $>$  threshold then
8:       addLandmarks(landMarkIds, landId)
9:     else
10:      newID  $\leftarrow$  addLandmark(landmark)
11:      addLandmarks(newID)
12:    end if
13:   end for
14:   return landMarkIds
15: end procedure                                 $\triangleright$  Return landmarks

```

---

**Method input:** The method takes as input a pointcloud as it is currently being read by the kinect sensor.

**Lines 3-4:** The downsampling and feature extraction are done through the pcl[12] library. A voxel grid is used to reduce the dataset size. A leaf size of approximately 3cm produces a good trade-off between precision and speed. The object representation used approach is similar to[17]. Instead of using the CSHOT descriptor, fpfh[22] histogram is used instead. A fast point feature histogram(fpfh) represents an angular signature between a point and its neighbors. After the fpfh estimation an angular signature of information between a point and its neighbors is acquired. The color signature of the cloud is being encoded with an approach similar to [33]. The color spectrum is discretized and what is extracted is the count of different color signatures between a point and its k nearest neighbors. Finally the position of every point is also given as input to the algorithm. The pipeline is presented in figure Fig. 10. The pipeline outputs a vector of  $\mathbf{x} = (x_s, x_c, x_a)$  where  $s$  represents a vector of space information,  $c$  a vector of colour information and  $a$  angular information.

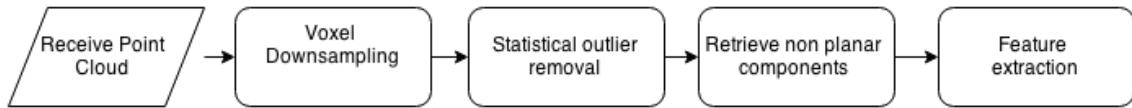

Figure 10: Point cloud modification pipeline.

**Lines 5:** The input of the method is the feature vector for every data point which is calculated in the previous steps. The clustering method is presented in section 4.3.

**Lines 6-12:** The correspondence of previously seen landmarks to current observations is computed here. Since the landmarks are distributions, statistical distances can be taken to perform the matching. For every observation, its distances with all the stored landmarks are calculated. calcBestSim returns the cluster with the highest similarity that exists in the database. If the similarity is high enough, correspondence is performed and the landmark is added to the landmark list to be send for update in the EKF, otherwise a new landmark is added and its ID is then added to the list.

**Lines 15:** The algorithm returns the list of the landmarks the robot currently encounters.

## 4.2. The data distribution

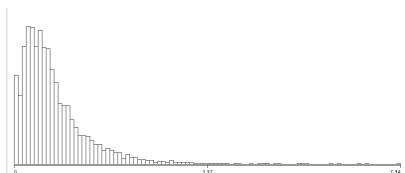

Figure 11: Exponential trend

Each point  $x$  in the cloud is represented as a tuple  $\mathbf{x} = (x^s, x^a, x^c)$  where superscript  $s$  represents spatial information,  $a$  angle information, and  $c$  color information. The method those features are extracted is explained in lines 3 and 4 of the general pipeline.

The object model is a mixture of distributions over the data with each object being modeled as  $F(\theta_t^k)$  where  $\theta$  represents the parameters of object  $k$  at time  $t$ . More specifically, each

set  $\mathbf{X}$  with  $n$  datapoints at time  $t$  is distributed as:

$$\mathbf{X}_{t,n} \sim F(\theta_t^k) = \text{Normal}(x_{t,n}^s | \mu_t, \Sigma_t) \text{Mult}(x_{t,n}^c | \delta_t) \text{Exp}(x_{t,n}^a | \lambda_t)$$

Where *Normal* is a three dimensional normal distribution with mean  $\mu$  and covariance  $\Sigma$  representing the positional distribution of the data; *Mult* is a Categorical multinomial distribution with parameter vector  $\delta$  representing the color distribution and *Exp* is an exponential with rate  $\lambda$  representing the angle distribution of the data within the cluster. This signature introduces a novel environment abstraction and the purpose of choosing such signature was to have both simple but also informative environment signatures captured by the model. The exponential distribution specifically was chosen to model angular information after empiric evaluation showed that it would provide a good fit for the angle signature distribution of the data. A typical angle signature distribution is shown in Fig. 11 and the exponential trend of data distances is trivial to distinguish.

Now that the object distribution is defined, the progression of the sufficient statistics at time  $t$  given  $t - 1$  given by:

$$\theta_t^k | \theta_{t-1}^k \sim \begin{cases} T(\theta_{t-1}^k) & \text{if } k \leq K_{t-1} \\ G_0 & \text{if } k > K_{t-1}. \end{cases}$$

Where  $T$  represents the transition kernel of the data given the previous state in the model. The case  $k > K_{t-1}$  represents the creation of a new cluster and  $G_0$  is the base distribution of the DDP. In our case, the conjugate priors of the distributions of the data were chosen to model the base distribution. Therefore,  $G_0$  is defined as:

$$G_0(\theta_t^k) = \text{NiW}(\mu_t^k, \Sigma_t^k | \kappa_0, \mu_0, \nu_0, \Lambda_0) \text{Dir}(\delta_t^k | q_0) \text{Gam}(\lambda_t^k | \alpha_0, \beta_0)$$

Where NiW is a Normal inverse Wishart distribution, Dir denotes a Dirichlet distribution, and Gam the Gamma distribution.  $\kappa_0, \mu_0, \nu_0, \Lambda_0, q_0, \alpha_0$  and  $\beta_0$  are parameters of the model. The generative process for the Dependent Dirichlet mixture model can be written for each timestep  $t$  as:

- 
1. Draw  $c_t \sim GPU(\alpha, \rho)$
  2.  $\forall k$  draw:  $\theta_t^k | \theta_{t-1}^k \sim \begin{cases} T(\theta_{t-1}^k) & \text{if } k \leq K_{t-1} \\ G_0 & \text{if } k > K_{t-1}. \end{cases}$
  3.  $\forall$  point  $n$  draw  $x_{t,n} \sim F(\theta_t^{c_t, n})$
- 

The transition kernel must satisfy[47]:

$$\int G_0(\theta_k) T(\theta_t^k | \theta_{t-1}^k) d\theta_{t-1}^k = G_0(\theta_k)$$

The equation means that the invariant distribution must equal its base distribution. A typical way of meeting this restriction and forcing the sampler to converge to the original target density[49] is to introduce a set of  $M$  auxiliary variables  $\mathbf{z}$  such that:

$$P(\theta_t^k | \theta_{t-1}^k) = \int P(\theta_t^k | z_t^k) P(z_t^k | \theta_{t-1}^k) dz_t^k$$

The transition kernel of the model can now be sampled by using the following formula:  
 $\theta_t^k \sim T(\theta_{t-1}^k) = T_2(z_t^k) \circ T_1(\theta_{t-1}^k)$  where:

$$\begin{aligned} z_{t,1:M}^k &\sim T_1(\theta_{t-1}^k) \\ &= \text{Normal}(\mu_{t-1}, \Sigma_{t-1}) \text{Mult}(\delta_{t-1}) \text{Exp}(\lambda_{t-1}) \end{aligned} \tag{3}$$

$$\begin{aligned} \mu_t, \Sigma_t, \delta_t, \lambda_t &\sim T_2(z_{t,1:M}^k) \\ &= \text{NiW}(\kappa_M, \mu_M, \nu_M, \Lambda_M) \text{Dir}(q_M) \text{Gam}(\alpha_M, \beta_M) \end{aligned} \tag{4}$$

where  $\mu_t, \Sigma_t, \delta_t, \lambda_t$  are posterior parameters given the auxiliary variables  $z$ .

### 4.3. Sequential monte carlo sampler

Sequential Monte Carlo(SMC) samplers for Dirichlet process mixture models were introduced by Doucet et al. [50] and serve as fast alternative to Markov Chain Monte Carlo and Variational Inference methods of performing posterior inference. SMC samplers have known strengths and weaknesses and are a good fit for the problem at hand, as their main theoretical disadvantage, the particle degradation is hard to occur at the minimal time horizon that the sampler is being used. We can now define the SMC sampler that will be used to perform inference on our model as follows:

---

#### Algorithm 3 SMC for DDPM

---

```

1: Input: Points  $\{x_{1,1:N_t}, \dots x_{T,1:N_t}\}$  with extracted features
2: Output: Clusters representing of the data
3: for  $t = 1, \dots, T$  do
4:   for  $l = 1, \dots, L$  do
5:     for  $iter = 1, \dots, S$  do
6:       Sample  $(c_t)^{(l)} \sim Q_1$ 
7:       Sample  $(\theta^k) \sim Q_2$ 
8:     end for
9:     for  $k = 1, \dots, K$  do
10:      Sample  $\Delta s_{t-1}^k \sim \text{Binom}((s_{t-1,N_{t-1}}^k)^{(l)}, \rho)$ 
11:      Set  $s_{t,0}^k = s_{t-1,N_{t-1}}^k - \Delta s_{t-1}^k$ 
12:      Sample  $((z_{t+1}^k)^{(l)}) \sim T_1((\theta_t^k))^{(l)}$ 
13:    end for
14:    compute particle weights  $w_t^l$ 
15:  end for
16:  Normalize and resample weights
17: end for

```

---

The process can be described as follows: For every time step  $T$  for every particle  $L$  and for every sample  $S$ , sample cluster indexes  $c_t^{(l)}$  from the proposal distribution  $Q_1$  and sufficient statistics from proposal distribution  $Q_2$ . After clusters assignments and sufficient statistics are sampled for all the samples and particles, perform the deletion step of the DDP and sample auxiliary variables with from the transition kernel of the elements that stayed in the clusters after the deletion steps. Compute the weights and perform the resampling.

#### 4.3.1 Gibbs updates

The proposal distribution  $Q_1$  is the probability of an assignment  $c_{t,n}$  given cluster sizes, parameters and concentration  $\alpha$ . Formally  $Q_1$  can be written as:

$$Q_1(c_{t,n}|s_{t,n}^k, \theta_t^k, \alpha) \propto \text{Cat}(s_{t,n}^1, \dots, s_{t,n}^K, \alpha) \times \begin{cases} F(x_{t,n}|\theta_t^{c_t}) & \text{if } k \leq K_{t-1} \\ \int P(x_{t,n}|\theta_t)G_0(\theta)d\theta & \text{if } k > K_{t-1}. \end{cases} \quad (5)$$

Where  $c_{t,n}$  represents cluster  $c$  of point  $n$  at time  $t$ ,  $s$  represents cluster sizes. The integral represents the posterior predictive distribution of the cluster times the base distribution with the parameters integrated out. More specifically, the analytic expression of the integral is:

$$\begin{aligned} \int P(x_{t,n}|\theta_t)G_0(\theta)d\theta &= \int \text{Normal}(x_{t,n}^s|\mu_t, \Sigma_t) \text{Mult}(x_{t,n}^c|\delta_t) \text{Exp}(x_{t,n}^a|\lambda_t) \times \\ &\quad \text{NiW}(\mu_t, \Sigma_t|\kappa_0, \mu_0, \nu_0, \Lambda_0) \text{Dir}(\delta_t|q_0) \text{Gam}(\lambda_t|\alpha_0, \beta_0) d\theta \\ &= \int \text{Normal}(x_{t,n}^s|\mu_t, \Sigma_t) \times \text{NiW}(\mu_t, \Sigma_t|\kappa_0, \mu_0, \nu_0, \Lambda_0) \\ &\quad \text{Mult}(x_{t,n}^c|\delta_t) \times \text{Dir}(\delta_t|q_0) \\ &\quad \text{Exp}(x_{t,n}^a|\lambda_t) \times \text{Gam}(\lambda_t|\alpha_0, \beta_0) d\theta \\ &= t_{\nu_0-1}(x_{t,n}^s|\mu_0, \frac{\Lambda_0(\kappa_0+1)}{\kappa_0(\nu_0-1)}) \times \prod_{j=1}^V \frac{\Gamma(x_{t,n}^c)}{\Gamma(q_0)} \times \\ &\quad \frac{\Gamma(\sum_{j=1}^V q_0)}{\Gamma(\sum_{j=1}^V x_{t,n}^c)} \times \text{Lomax}(\alpha_0 + s_{t,n}^c, \beta_0 \sum_{j=1}^V x_{t,n}^c) \end{aligned} \quad (6)$$

Where  $t$  represents student's t-distribution with  $\nu$  degrees of freedom, Lomax represents Lomax distribution with shape and scale,  $\alpha$  and  $\beta$  respectively and the rest represent a Dirichlet-Multinomial(aka DirMul) distribution. The formulas of the posterior predictive distributions can be found in the literature with [48] being a good example.

The conjugacy of the base and prior distribution allows for an easy sampling formula for proposal distribution  $Q_2$  which is of the form:

$$\begin{aligned} Q_2(\theta_t^k|\theta_{t-1}^k, x_t^k, z_t^k) &\propto F(x_t^k|\theta_k) \times T_2(\theta_t^k|z_t^k) \\ &= \text{NiW}(\mu_t^k, \Sigma_t^k|\kappa_n, \mu_n, \nu_n, \Lambda_n) \text{Dir}(\delta_t^k|q_n) \text{Gam}(\lambda_t^k|\alpha_n, \beta_n) \end{aligned} \quad (7)$$

With:

$$\begin{aligned}\kappa_n &= \kappa_0 + N, \nu_n = \nu_0 + N, \mu_n = \frac{\kappa_0}{\kappa_0 + N} \mu_0 + \frac{N}{\kappa_0 + N} \bar{x}^s \\ \Lambda_n &= \Lambda_0 + s_x^s, q_N = q_0 + \sum_n x_i^c, \alpha_n = \alpha_0 + N, \beta_n = \beta_0 + \sum_n x_i^a\end{aligned}\quad (8)$$

Where  $\bar{x}$  defines the sample mean for the elements assigned at cluster  $c$ ,  $s_x$  the sample variance and  $N$  denotes the number of observations[52].

#### 4.3.2 Weight updates

Finally, the weight update step is defined as follows: On every time step  $t$  the weight of particle  $l$  is calculated as:

$$w_t^{(l)} = \frac{P(c_t^{(l)}, \theta_t^{(l)}, x_t | \theta_{t-1})}{P(c_t^{(l)}, \theta_t^{(l)} | \theta_{t-1})} \quad (9)$$

Using Bayes rule, the numerator can be written as:

$$P(x_t, | c_t^{(l)}, \theta_t^{(l)} | \theta_{t-1}) \times P(c_t^{(l)}, \theta_t^{(l)} | \theta_{t-1}) \quad (10)$$

Which can be calculated using equations  $Q_2$  and  $Q_1$  for the first and second part respectively. After the particle weights are normalized particles are drawn with probability proportional to their weights.

#### 4.4. Decision Layer

Once the points of the current iteration are clustered, the clusters are passed as input to the decision layer. The decision layer calculates the similarity of the current clusters to past ones; if the similarity is high enough the clusters are considered to be part of the same landmark. To do that, distance measures between the stored clusters and the ones that are inferred at the current iteration of the algorithm must be defined. Distances between distributions are called divergences and a large amount of literature on divergences exists.

Every cluster consists of a three part distribution as it was defined in section 4.2. To define a distance measure between cluster, individual distances between all the distribution parts will be defined. More specifically let  $l$  be the distribution of a cluster encountered in the past and  $o$  the distribution of a currently observed cluster.  $l$  and  $o$  can be decomposed into 3 parts:  $l_G, l_C, l_E$  where G,C and E stand for Gaussian, Categorical and Exponential respectively. With that notation the distances between those distributions can be defined. For each individual landmark distribution  $l$  and observation distribution  $o$  the distances computed were the following: A Wesserstein( $l_G, o_G$ ), a Kullback-Leibler( $l_G, o_G$ ), a SquaredHellinger( $l_E, o_E$ ), a Kullback-Leibler( $l_E, o_E$ ) and Kullback-Leibler( $l_C, o_C$ ).

With that in mind the distance between every distribution can be transposed to a vector where each element represents a specific distance between the two distributions. That way, deciding if a cluster is part of a landmark that has been encountered before is now a problem of finding

the optimal decision boundary given the distances at hand. For the purposes of this thesis, the decision boundary of an observation being a landmark or not was chosen by empiric evaluation of the landmarks. It is of course possible to learn the optimal decision boundary but due to time restrictions a simpler decision making approach was chosen instead.

## 4.5. Complexity

The complexity can be decomposed into three parts. The cloud downsampling, the clustering and the decision making process.

$$O(\text{total}) = O(\text{filter}) + O(\text{cluster}) + O(\text{decision})$$

**Downsampling:** The complexity of the cloud downsampling pipeline can be decomposed to the one of its components. This means that the decomposed complexity is defined as follows:

$$O(\text{filter}) = O(\text{Downsampling} + \text{Stat Removal} + \text{RANSAC} + \text{FPFH} + \text{Color est})$$

Voxel downsampling searches for neighbors within a distance defined by the user and keeps an average value that equally represents the cloud. Since the operation involves searching for neighbors of a point, and since search operations take  $O(\log n)$  time where  $N$  is the number of points within the cloud, the complexity of voxelGrid downsampling is  $O(k \log n)$  where  $k$  is the number of neighbors and  $n$  the number of points in the cloud. Statistical outlier removal searches for  $k$  nearest neighbors and removes those whose deviation is passed a certain threshold. Given that search operations take  $O(\log n)$ , for  $k$  neighbors, the complexity is  $O(k \log n)$ . The same assumption regarding the averaging computations is done here. A high amount of research has been done regarding the optimal complexity of RANSAC [51]. RANSAC has a complexity of  $O(k + m_s * N)$  where  $k$  is the maximum amount of iterations defined by the user,  $m_s$  the average number of models per sample  $N$  the number of data points. FPFH operations have a complexity of  $O(nk)$  as given in [22]. Finally, for the operation of color estimation, the  $k$  nearest neighbors are chosen and some constant operation is performed on them. The complexity here is similar to Statistical outlier removal since operations after the search are assumed to take  $O(1)$  time. The complexity for color estimation then becomes  $O(k \log n)$  where  $k$  is the number of neighbors,  $n$  the number of points.

The downsampling pipeline has a total complexity of:

$$O(\text{filter}) = O(k_0 \log n_{\text{init}} + k_1 \log n_1 + k_2 + m_s * n_2 + n_3 k_3 + k_4 \log n_3) \quad (11)$$

The different  $k$  indexes represent the number of neighbors defined for every operation. The  $n$  represents the number of points used as input. Using the notation of equation 11,  $n_{\text{init}}$  defines the whole cloud,  $n_1$  the cloud after operation 1,  $n_2$  the cloud after operations 2 and so on.

**Clustering:** The complexity of the SMC sampler is defined in [33] as  $O(TLKN)$  where  $T$  defines the time frames,  $L$  the number of particles,  $K$  the number of clusters,  $S$  the number of samples, and  $N$  the size of the dataset.

$$O(\text{cluster}) = O(TKLSN)$$

**Decision making:** The decision making takes  $O(\kappa * l^2)$  computational time where  $\kappa$  defines the number of clusters output by the sampler and  $l$  the number of landmarks currently stored in the database. This number can be further reduced by taking for example only landmarks that are nearby the cluster, but optimizing the decision making performance is outside the scope of this project.

Finally, with some notation abuse, the final complexity of the method can then be defined as:

$$\begin{aligned} O(filter) + O(cluster) + O(decision) = \\ O(k_0 \log n_0 + k_1 \log n_1 + O(k_2(t_M) + m_s * n_2) + n_3 k_3 + k_4 \log n_3) + O(LKS_n_3) + O(\kappa * l^2) = \quad (12) \\ O(k_0 \log n_0 + k_1 \log n_1 + k_2(t_M) + m_s * n_2 + n_3 k_3 + k_4 \log n_3 + LKS_n_3 + \kappa * l^2) \end{aligned}$$

The complexity as defined in equation 12 depends on the initial reduction of the voxel downsampling. As the voxel leaf size parameter decreases and the downsampling outputs a larger cloud, the precision as well as the computing time of the method increases. Since in this thesis the research was directed towards online SLAM methods, the leaf size was modified so that the cloud the time requirements for online landmark tracking were met.

#### 4.6. Landmark size

The basic block of this algorithm is a cluster containing an environment signature. In order to be able to compute how scalable the method is, the size a single cluster requires to be stored will be calculated. Each cluster is represented by the parameters of the distributions it contains; these values are passed in a single row in a database[53]. According to the database manual the maximum number of memory a single landmark can require is 260 bytes. Calculations in the results section are done using 260 bytes as a unit cost of the method.

## 5. RESULTS

### 5.1. Simple datasets

In this section the algorithm will be tested against a simple dataset. That will make easier the conceptual extension to more complex clouds that will be used when mapping the environment. In order to test the sampling as well as the decision layer of the algorithm, a simple dataset provided by the pcl[12] library was used. More specifically, a cloud consisting of two milk cartridges with different colors and poses was used. The initial cloud is shown in Fig.12.

The cloud was first given as input to the downsampling and feature extraction pipeline. The reduced cloud (top left Fig.12) was then passed as input to the sampler and the clustering results are shown in Fig.12. The downsampling results in a significantly smaller cloud and this cloud along with feature-information needed to perform the clustering are given as input to the sampler. The sampler outputs a mixture of distributions that fits the input data. The clustering output is shown in Fig.12 with the top right being the Gaussian distributions inferred, bottom left the exponential and bottom right the categorical representing the color information of the cloud. The height of the objects leads to distribution with high variance in the z axis. The sampler outputs 3 clusters for the data and it can be seen that the change in angular information of the box leads the sampler to assign two distributions in the left milk box cloud. The color information is captured correctly in the structures and that was expected since the data had distinct colour signatures.

UUID 1

3	0	2.43346e-07	0	0.481313	0

After the structure is clustered, distances between the elements can be calculated. Table 5.1 shows the distances between every cluster shown in Fig.12. It can be seen that the first two landmarks have small distances in their Gaussian counterparts since they represent nearby areas and objects in the cloud that are very far apart. The angular distances between them are also not very large. The distinct colors of the milk boxes make the color signatures of the clusters distinct. The calculated distances are then given to the decision layer to calculate if the clusters currently calculated are part of landmarks previously encountered. An example with more complex color signatures is shown in Fig.13. The clouds are now given a mixture of colors and this is passed to the color signature inferred on every cluster in Fig.13. In this case the sampler outputs 2 clusters

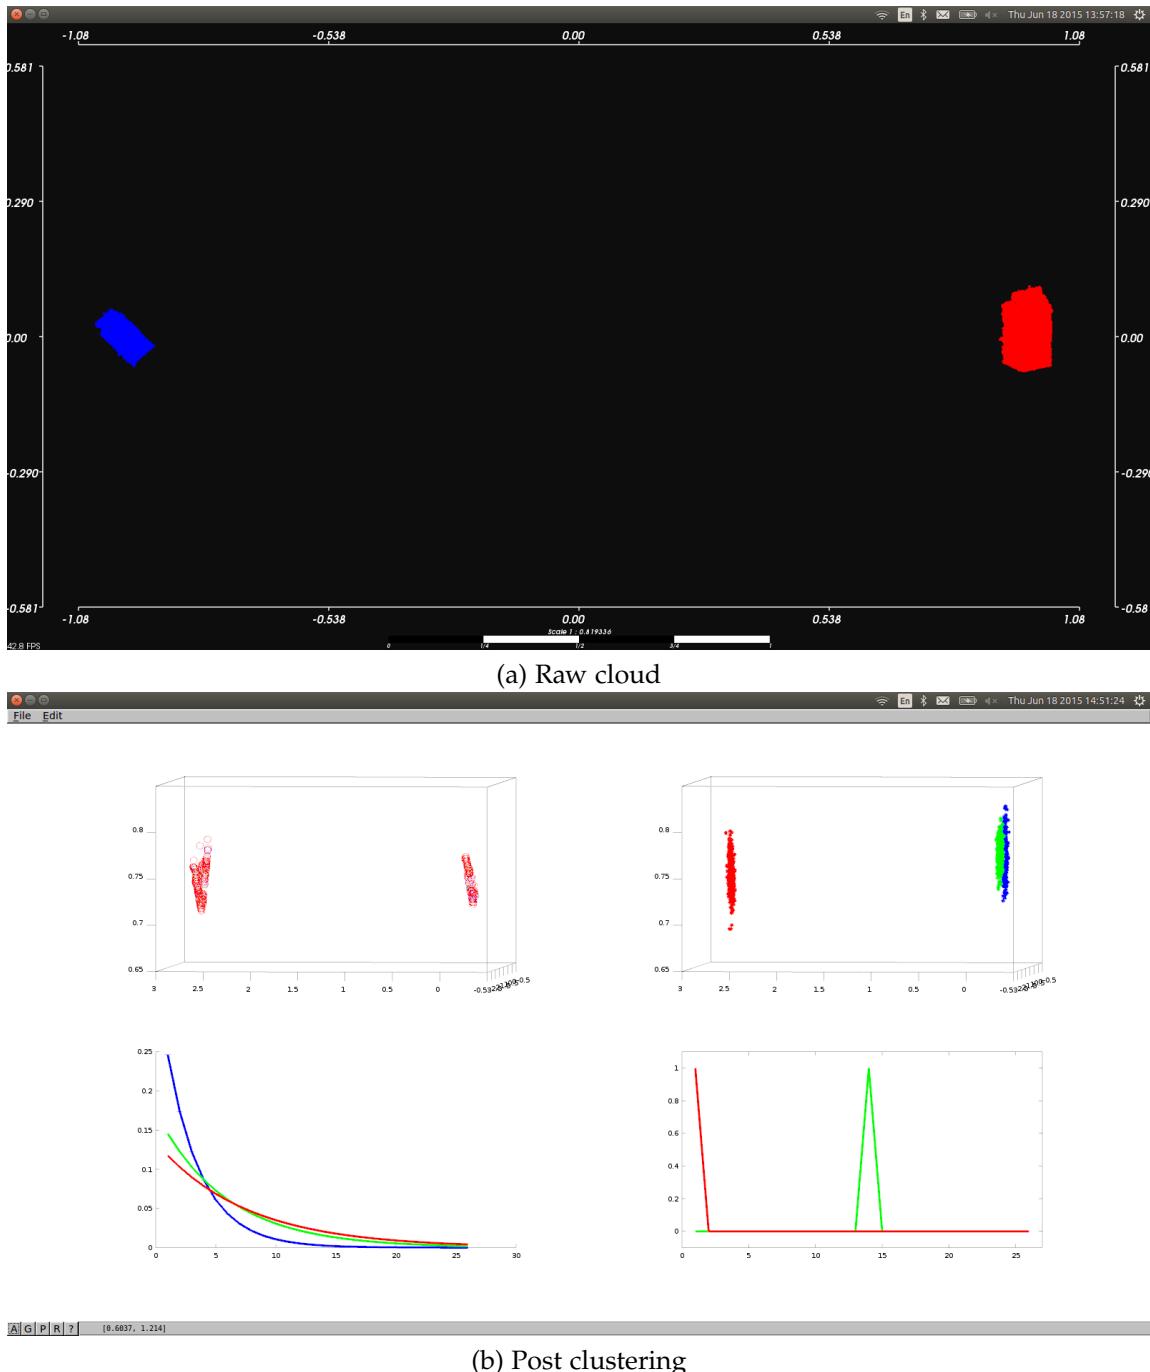

Figure 12: Initial data along with the distributions inferred

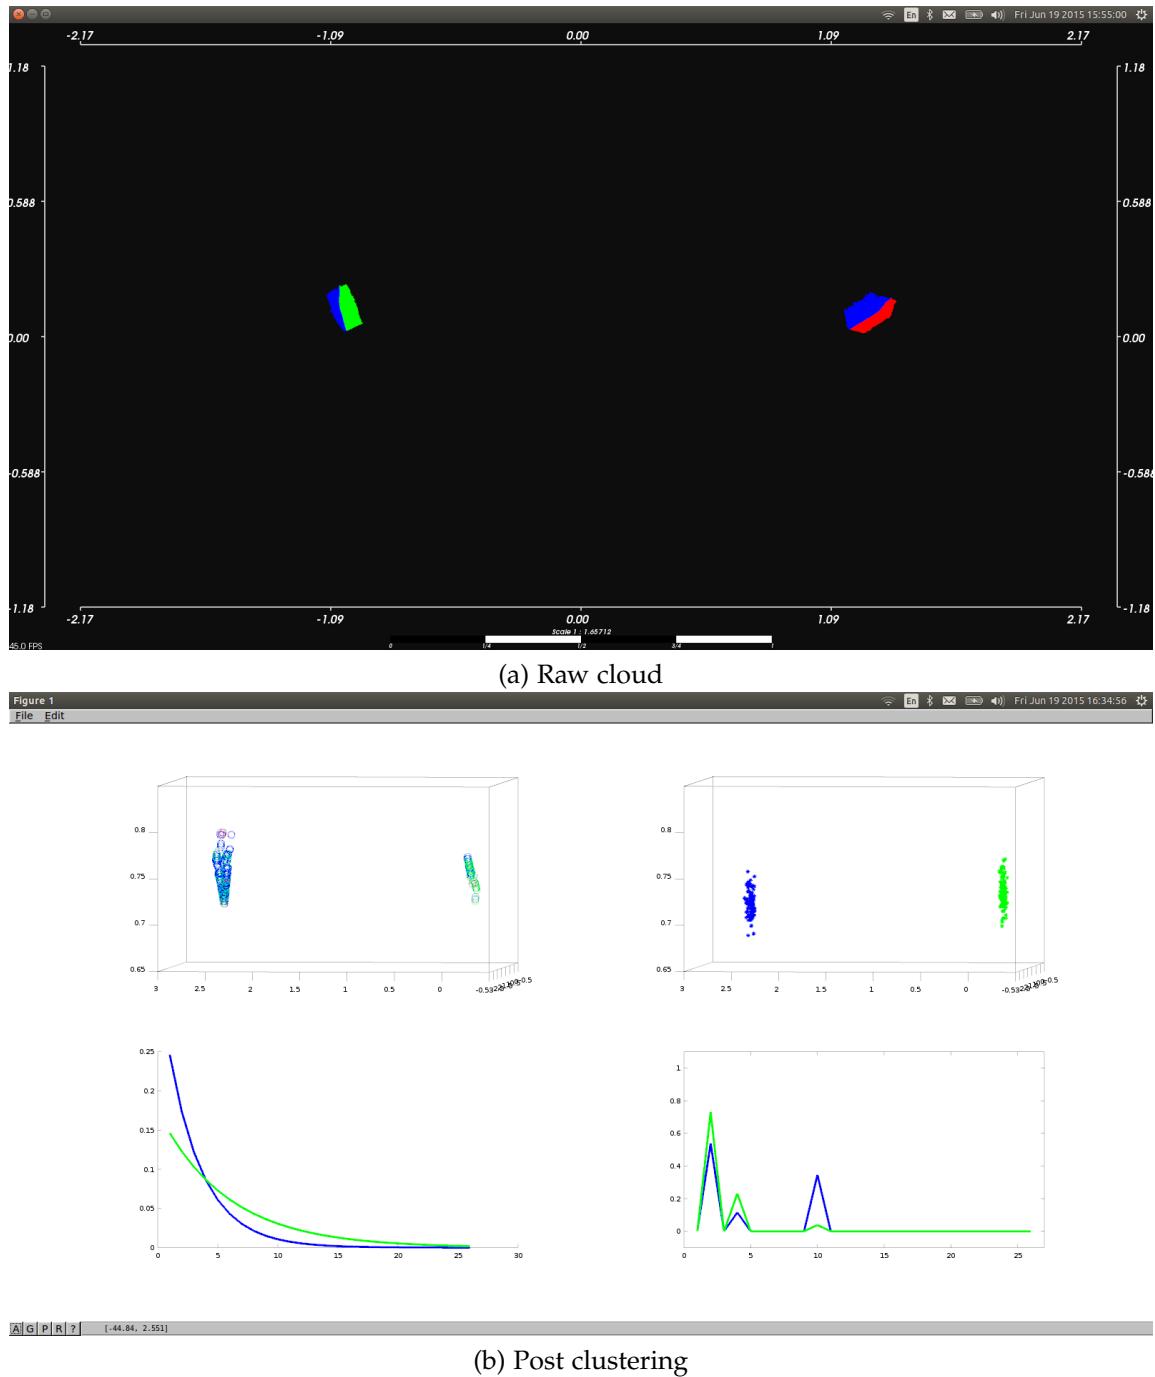

Figure 13: More complicated color distributions

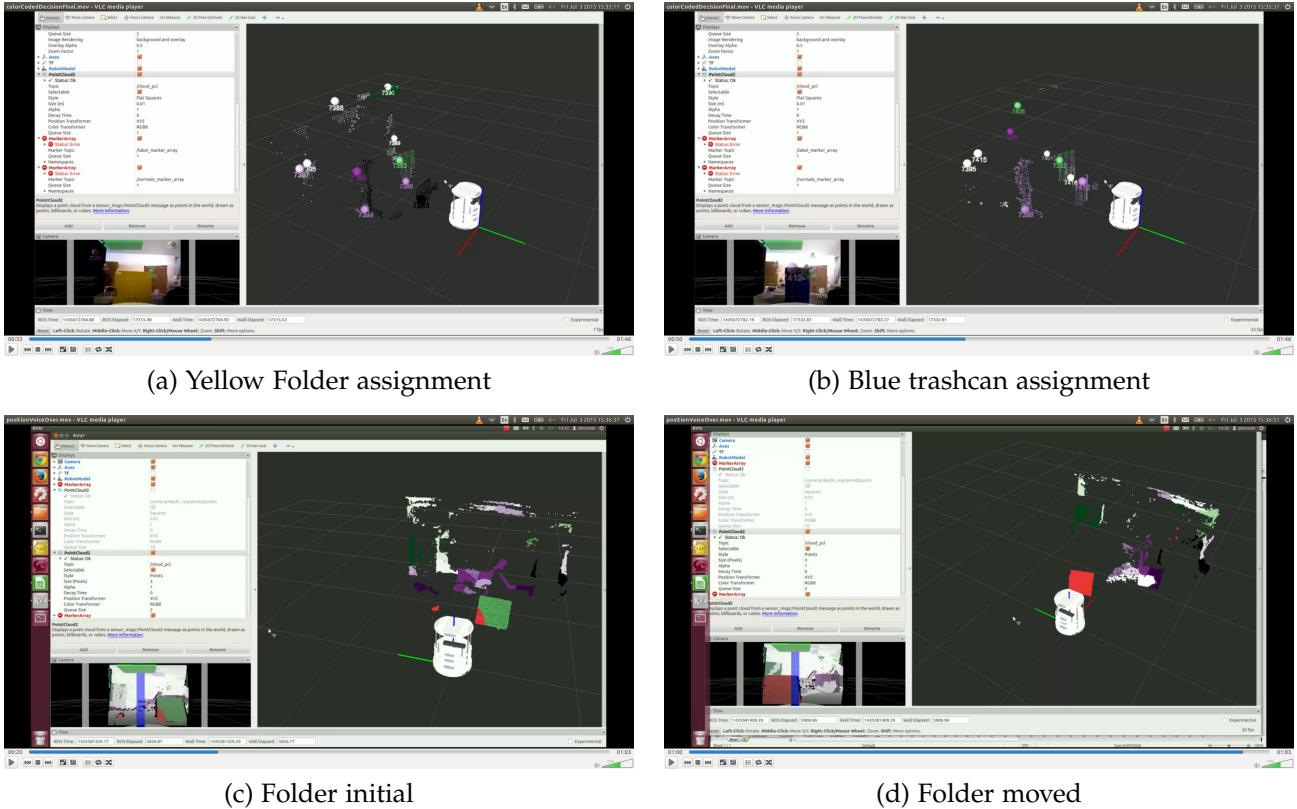

Figure 14: The colour and position boudnary is displayed in these pictures

and the color signatures capture the more complex color signatures as well as the expected overlap correctly.

## 5.2. Expressiveness and decision layer

Are such representations rich enough to be used as references points when performing SLAM? To test the expressive strength of the representation, experiments were performed to test how the representation in combination with the decision layer differentiated over different objects in the cloud. The decision boundary of the pipeline can be decomposed into three basic parts; a positional, a color and an angular boundary. Fig.14 shows the behavior of the decision layer with respect to the Gaussian(positional) and Categorical(color) parts.

In the first picture of Fig.14 the yellow folder along with some of its environment to the left are being assigned to landmark with id 7386. The folder is then removed and a blue trashcan is put in its place. The folder and the trashcan are similar in size and due to that their Gaussian counterparts will not have large distances. Their main difference lies in the color signature they carry. Since the distance in their color is substantial, a new landmark with id 7412 is created to

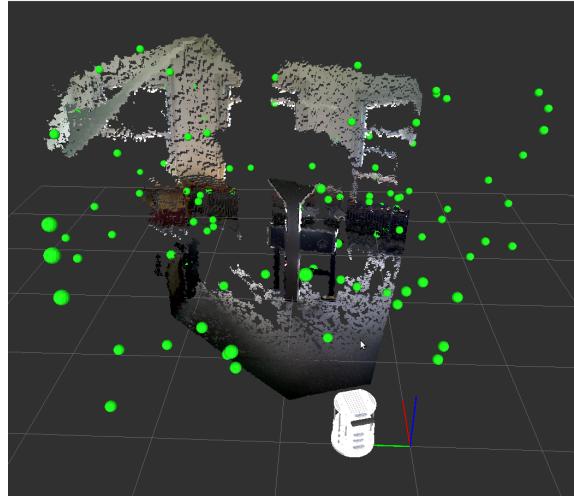

Figure 15: SLAM session using the pipeline.

capture the change in the signature of the environment at that place of the map. The different landmark assigned to the cluster can be seen the second picture in Fig.14. The positional decision boundary is displayed in the third and fourth picture of Fig.14. In the initial position the yellow folder is assigned to the green landmark of the cloud. As the object is moved a different position in the cloud, it is being assigned to a different cluster. The reason the cluster is assigned to multiple landmarks is due to the fact that the folder is decomposed to several clusters and each one of them is being assigned to a different part of the cloud with respect to their position. This can be seen in the fourth picture of Fig.14 where the bottom left of the folder is being assigned to the red cluster.

The exponential part of the distribution is responsible for the angle signature elements within a cluster have. Having a very strict limit in the angle distribution can lead to very small clusters and subsequently to a high amount of landmarks within the data. Practical evaluation has shown that using an angle limit that is close to the average distance between angle signatures produces stable results and reasonably sized landmarks in the cloud.

### 5.3. EKF-SLAM experiments

The pipeline was used in real life scenarios as a sensor model in a Landmark based EKF SLAM algorithm and was tested in its speed and memory requirements. Fig.15 shows an end result of a SLAM session using the pipeline as a sensor model. The yellow spheres represent the landmarks extracted during the SLAM session with every sphere representing the environment signature at the specific part of the map; noisy cloud readings were taken from a kinect sensor mounted on the robot.

The compression that the method introduces is not directly observable. As the environment is being reduced from a cloud to a landmarks, the memory needs change from using pointclouds to using the landmarks extracted in those clouds. Since every landmark represents a signature of the environment at this particular point, the compression is done by reducing a high amount of points

to that specific signature. The number of parameters needed to define the three distributions in the signature is all the information this method requires and hence the memory gains are substantial.

### 5.3.1 Speed

Are the methods fast enough to be used in online SLAM problems? As was shown in the complexity session, the speed is dependent on the initial downsampling of the pipeline. If the initial downsampling performed on the cloud is intense, there will be significant information loss but the speed of the method will increase. Conversely if the downsampling is not intense the speed of the method will decrease making the pipeline unable to handle online data streams. The speed of the method was tested on a mid level as well as on a high level machine to display the differences in time needed to perform the operations. The benchmark results of a machine running on a pentium i5-3210M and on a pentium i7-3610QM are shown in table 5.3.1.

Pentium i5-3210M				
Leaf Size	Downs Time	Cloud size	Sampling	Matching
1m	0.908768	9	0.0290296	0.00218081
50cm	0.914169	32	0.0112929	0.00243211
30cm	1.07862	79	0.0138666	0.00126673
10cm	1.1764	654	0.0712596	0.00154977
5cm	1.75907	2391	0.215594	0.00181846
1cm	14.3283	25556	5.06356	0.854803
Pentium i7-3610QM				
Leaf Size	Downs Time	Cloud size	Sampling	Matching
1m	0.675993	7	-	-
50cm	0.779975	30	-	-
30cm	0.676315	66	-	-
10cm	0.746999	488	-	-
5cm	0.878036	1827	0.132831	0.00281951
1cm	1.11554	18487	2.69855	0.0021291

The leaf size directly affects the time the cloud takes to be processed in the pipeline as well as the time the sampling takes afterwards. As shown in the table, a leaf size between 1-5cm provides a good balance between speed and precision. Matching benchmarks the time it takes for the method to match all the landmarks to landmarks in the database, or create new ones. It must be noted that adding new landmarks can be a time consuming operation compared to just matching to existing ones. In fact matching everything to existing takes a very small amount of time and can be therefore disregarded.

### 5.3.2 Memory requirements

“Is the compression created by the methods significant?” The memory requirements are shown in Fig.16 as a function of strength parameter alpha. The compression that the method introduces is significant since even for a very high value of alpha, since the memory needs of the landmarks are

smaller than 30KB of memory total. Mapping the same environment using the RTAB mapping method, results in maps that average 84MB of memory which leads to a significant compression ratio of 1/2800.

The memory requirements of the method are a function that is directly affected to the  $\alpha$  strength parameter of the sampler. As the  $\alpha$  parameter increases, the sampler will output more clusters on every iteration. The higher amount of cluster will result a higher amount of landmarks and, consequently, in larger memory requirements in the method.

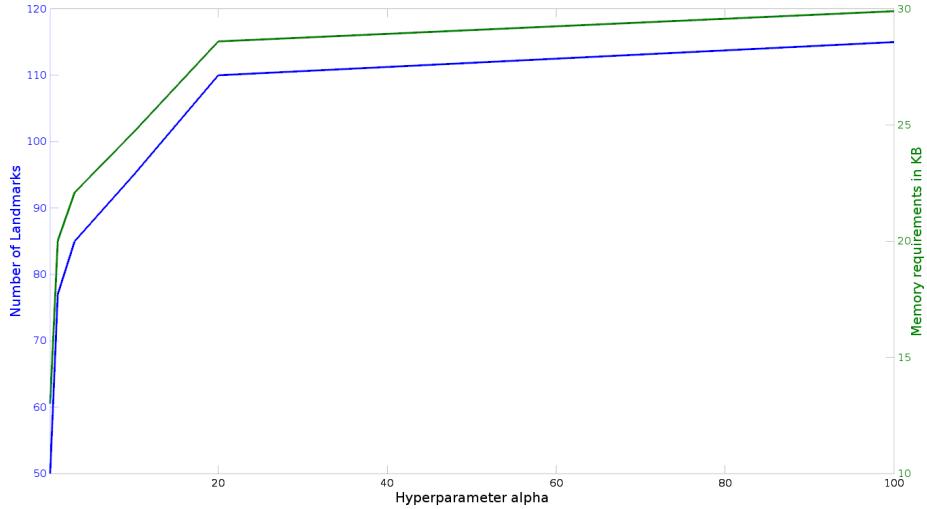

Figure 16: Memory Requirements as a function of strength parameter  $\alpha$ .

As can be seen, the number of landmarks follows the logarithmic trend of the distribution in relation to  $\alpha$ . Increasing the alpha value more will not make the algorithm follow the logarithmic trend indefinitely. That is due to the fact that as the alpha increases, the constant decision layer has an upper bound to the number of landmarks it can have. This means that the algorithm will keep adding landmarks until the environment saturates and no new landmarks can be added. It must also be noted that as the alpha parameter is set to higher numbers, the sampler outputs more clusters making it more accurate of the environment descriptor it outputs, but also takes more time, making it non feasible to use this in real time mapping scenarios. Values of alpha between 1 and 10 provide a robust but also fast enough sampler that can be used in online mapping scenarios.

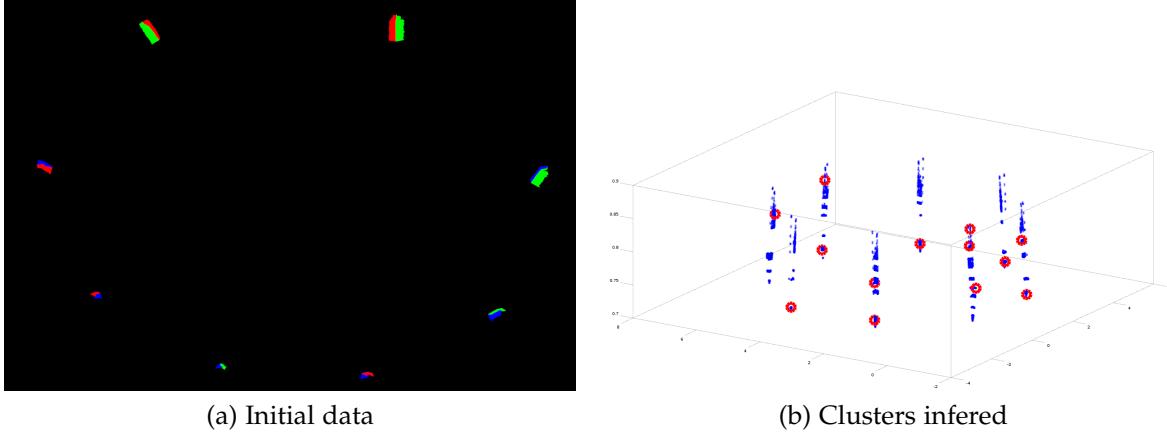

Figure 17: Unsupervised entity extraction.

## 6. DISCUSSION

### 6.1. Unsupervised learning

It is important to note the implications of having a pipeline that is based on a Dependent Dirichlet Process i.e. an unsupervised learning algorithm. Due to the unsupervised nature of the method, the elements of the cloud will be clustered as the algorithm sees (statistically)fit. This means that there will be clusters in the cloud that will be small in size and will contain just parts of objects and, conversely, clusters are large contain more than objects. The environment is clustered in chunks that need not be semantically sound. One such example is shown in Fig.17 where multiple milk cartridges are either clustered as single entities or part of larger clusters.

### 6.2. Clustering layer

An important limit of the pipeline exists with respect to the Dirichlet hyper-parameter  $\alpha$ . During the clustering, choosing a correct value for the hyper-parameter  $\alpha$  is important. Having the sampler run with a very low  $\alpha$  can lead to the whole cloud being assigned a single cluster. Having every point in the cloud being part of the same cluster leads to a significant amount of information loss as no region specific information is propagated to the clusters output. Fig.[18] shows the behaviour of the sampler for  $\alpha$  values lower than 1. The clusters are color coded in the downsampled cloud, and it can be seen that only one cluster is output by the sampler.

On the other hand, having a very large  $\alpha$  can lead to a very large amount of clusters being output by the sampler every time. That can lead to a non converging pipeline since every time a new landmark that does not fit the landmark database is output. This leads to many small clusters with each containing a small number of points. Furthermore, having a high value in the hyperparameter leads to a slower sampling process since the complexity of the sampler is  $O(TKLSN)$  where  $K$  is the number of clusters. Fig.[11] displays the behavior of the sampler for very large values  $\alpha$ . The landmarks extracted from a single cloud are shown as spheres; it can be

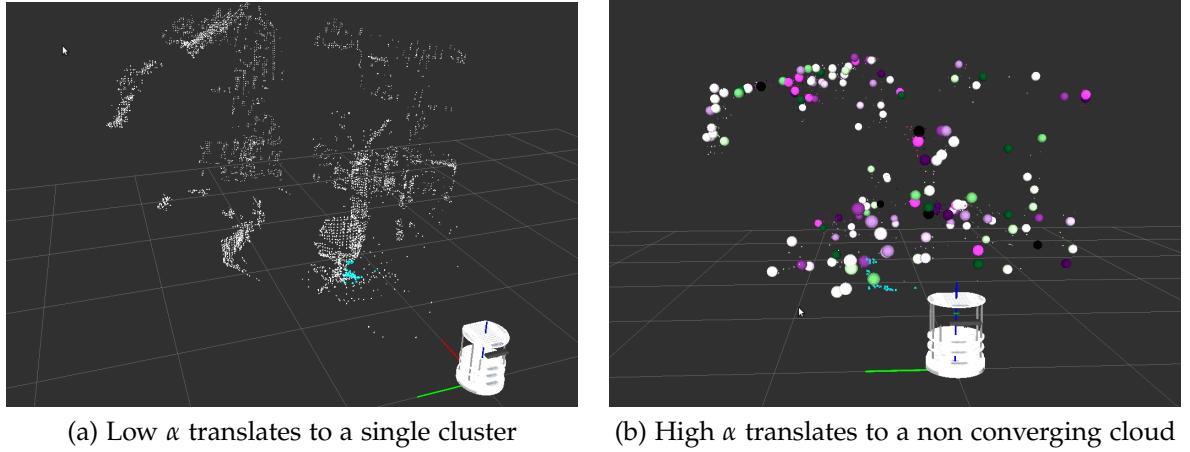

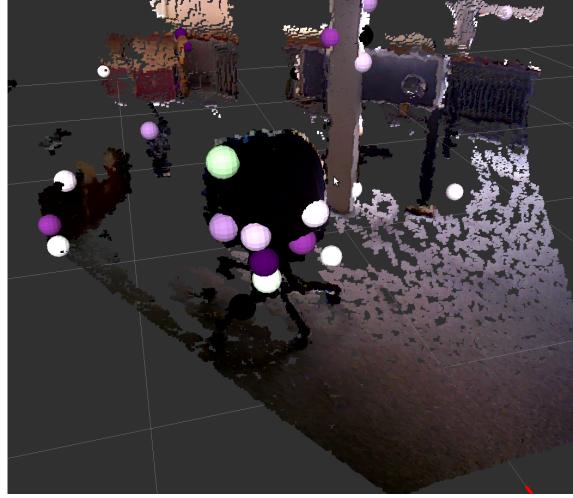

Figure 18: Extreme use cases.

seen that the cloud is not visible and the majority of the points is considered a landmark of its own.

### 6.3. Decision layer

The restrictions introduced by the decision layer are straightforward due to the simple approach of the decision layer. Taking very small distances in the distance threshold operation can lead to pipeline that continuously adds new landmarks to the database. An example is shown in Fig. 6.3 where limiting the landmark matching operation to very small exponential distances, leads to a cloud where objects are decomposed to many entities that also differ on every iteration. Spheres represent landmarks and it can be seen that the chair is being assigned to many landmarks using the pipeline with this setup. That means that very strict limits lead to a non converging pipeline with respect to the landmarks it outputs. Furthermore, since the number of landmarks is also a function of noise, areas of the cloud that are near the maximum range of the sensor can lead to different landmarks added frequently. These issues can be tackled by having a less strict limit in the operation that defines what is considered a landmark the sampler has encountered before or not.

(a) Very strict decision limits lead to multiple entities on a single

## 7. CONCLUSION AND FUTURE WORK

In this thesis a novel cloud representation by using Bayesian methodologies was introduced. Its compression strength, expressiveness and speed were presented as well as how it could help tackle the compression problem of lifelong mapping. The discussion section showed ways that wrong initial parameters can lead the pipeline produce sub-optimal results as well as described its clustering behaviour given its unsupervised nature. There is a number of directions in which the method could be improved. Choosing more complex environment signatures could increase the expresional strenght of the sampler making it easier to represent with higher precision more complex structures. Furthermore, since the sampler clusters parts of environment, it would be interesting to see how a hierarchical approach would change the result of the clustering. Hierarchical dependent Dirichlet processes would be interesting extensions since such tools would both have the ability to capture structures in a hierachal way not just as chunks of the environment as well as be able to handle the dynamic component that lifelong mapping problems introduce. Furthermore, having a more complex decision layer would also increase the robustness of the method making it able to handle more complex environment structures. Finally, all those additions could help tackle lifelong mapping problem as a whole in a fully Bayesian manner.
